ABSTRACT

Physical exercise modulates food reward and helps control body weight. The endogenous μ-opioid receptor (MOR) system is involved in rewarding aspects of both food and physical exercise, yet interaction between endogenous opioid release following exercise and anticipatory food reward remains unresolved. Here we tested whether exercise-induced opioid release correlates with increased anticipatory reward processing in humans. We scanned 24 healthy lean men after rest and after a 1-hour session of aerobic exercise with positron emission tomography (PET) using MOR-selective radioligand \(^{[11]}\)C-carfentanil. After both PET scans the subjects underwent a functional magnetic resonance imaging (fMRI) experiment where they viewed pictures of palatable versus non-palatable foods to trigger anticipatory food reward responses. Exercise-induced changes in MOR binding in key regions of reward circuit (amygdala, thalamus, ventral and dorsal striatum, orbitofrontal and cingulate cortices) were used to predict the changes in anticipatory reward responses in fMRI. Exercise-induced changes in MOR binding correlated negatively with the exercise-induced changes in neural anticipatory food reward responses in orbitofrontal and cingulate cortices, insula, ventral striatum, amygdala, and thalamus: higher exercise-induced opioid release predicted higher brain responses to palatable versus non-palatable foods. We conclude that MOR activation following exercise may contribute to the considerable inter-individual variation in food craving and consumption after exercise, which might promote compensatory eating and compromise weight control.

Keywords: brain imaging, food reward, opioid release, physical exercise
INTRODUCTION

Physical exercise helps control body weight by modulating various physiological signalling pathways that govern energy homeostasis and regulate appetite and food intake (Schubert, Sabapathy, Leveritt, & Desbrow, 2014). Yet without calorie restriction, exercise alone is an ineffective means for weight loss (Shaw, Gennat, O’Rourke, & Del Mar, 2006; Swift, Johannsen, Lavie, Earnest, & Church, 2014): compensatory changes in dietary caloric intake following exercise contribute to variability in weight loss outcomes (Thomas et al., 2012), and these changes likely reflect differences in exercise-induced alterations in hedonic responses to food (Finlayson, Bryant, Blundell, & King, 2009; Finlayson et al., 2011). As hedonic properties of palatable foods bear strong automatic incentives that may trigger food consumption even beyond energy requirements, exercise-induced modulation of brain’s reward processing may be important for compensatory eating after physical exercise.

Behavioural and neuroimaging studies in humans have revealed altered hedonic and motivational responses to food following exercise. A single exercise session reduces chocolate craving and consumption (Oh & Taylor, 2012) and decreases preference for high versus low-fat foods (McNeil, Cadieux, Finlayson, Blundell, & Doucet, 2015). At the neuronal level, functional magnetic resonance imaging (fMRI) studies have revealed altered haemodynamic responses to visual images of high versus low caloric foods within brain regions implicated in reward processing following acute (Crabtree, Chambers, Hardwick, & Blannin, 2014; Evero, Hackett, Clark, Phelan, & Hagobian, 2012) and long-term exercise (Cornier, Melanson, Salzberg, Bechtell, & Tregellas, 2012), implicating altered anticipatory reward processing. Although these findings in general suggest that physical exercise suppresses subsequent energy intake and food craving, these effects may vary considerably...
between individuals. For example, a single bout of exercise increased palatability and craving for food as well as preference for energy dense appetizing foods in individuals who were more prone to increase their post-exercise energy intake in comparison with individuals whose energy intake did not change or even decreased (Finlayson et al., 2009). Furthermore, increased food palatability and increased preference for high-fat sweet foods acutely after exercise predicted smaller weight loss outcomes after 12-week exercise intervention in obese individuals (Finlayson et al., 2011).

Despite progress in understanding the effects of exercise on hedonic processing of food, the underlying neurochemical mechanisms remain unrevealed. The endogenous mesolimbic opioid system and particularly the µ-opioid receptors (MOR) are linked to both incentive motivation and hedonic functions, and are involved in generating pleasurable sensations of consuming palatable foods (Nummenmaa & Tuominen, in press; Peciña & Smith, 2010). Animal studies have shown that MOR agonist administration increases food intake (Gosnell & Levine, 2009; Peciña & Smith, 2010) and may specifically increase the preference for high fat diet (Taha, 2010). Recent human positron emission tomography (PET) studies have revealed that food consumption triggers endogenous opioid release (Burghardt, Rothberg, Dykhuis, Burant, & Zubieta, 2015; Tuulari et al., 2017) and that continuous overstimulation of the MOR system following excessive eating may result in subsequent downregulation of the MOR in obesity (Karlsson et al., 2016; Karlsson et al., 2015), suggesting a link between MOR and food consumption in humans. We have also previously demonstrated that in healthy subjects, lower baseline MOR binding predicts higher anticipatory food responses (Nummenmaa et al., 2017), suggesting a direct link between brain opioid function and food reward processing. Although we did not previously find an overall change in MOR binding after moderate-intensity physical exercise (Saanijoki et al., 2018), we noted considerable between-subject variability in MOR responses: increased endogenous
Corresponding Author: Dr. Jussi Hirvonen

opioid release was correlated with increased euphoria. This variability might also explain individual differences in changes in food reward processing after exercise.

In this multimodal neuroimaging study, we sought to determine whether acute exercise and subsequent release of endogenous opioids predicts changes in neuronal responses to anticipatory food reward. The subjects were scanned two times: after 60 min moderate-intensity aerobic exercise and after rest. Both conditions were followed by measurement of MOR availability with $^{11}$Ccarfentanil PET, and estimation of anticipatory reward responses triggered by viewing palatable versus non-palatable food pictures during fMRI. We hypothesized that opioid release after exercise, as indexed by decreased MOR-availability, would be associated with increased anticipatory food reward as measured using fMRI.

MATERIALS AND METHODS

Participants

The study was conducted in accordance with the Declaration of Helsinki at the Turku PET Centre, University of Turku and Turku University Hospital (Turku, Finland). The Ethics Committee of the Hospital District of Southwest Finland approved the study protocol. Twenty-four men met the eligibility criteria (Saanijoki et al., 2018), signed ethics-committee approved informed consent forms, and were admitted into the study (Table I).

Study design

Study design has been described in details previously (Saanijoki et al., 2018). Timeline for experimental sessions is shown in Figure 1. Briefly, all participants underwent two PET and fMRI scans on separate days: after rest and after a session of moderate-intensity aerobic
Corresponding Author: Dr. Jussi Hirvonen

exercise. Participants fasted for three hours before the scans and were told not to use caffeine-containing products, alcohol, or perform any physical exercise the day before the scans. The order of the scans was counterbalanced across participants.

Exercise session included 60 minutes of continuous aerobic cycling (Tunturi E85, Tunturi Fitness, Almere, The Netherlands) at workload in the middle between aerobic and anaerobic thresholds predetermined individually in maximal exercise test (described in details in Saanijoki et al., 2017) (mean workload during exercise 157 (SD 47) W; 53 (SD 7) % from Load\textsubscript{max}; range 70—265 W; average heart rate during exercise 144 (SD 15) beats per min; 74 (SD 7) % from maximal heart rate). Two of the participants had a slightly longer exercise session (76 and 77 minutes instead of programmed 60 minutes) due to unexpected delay with radiotracer supply. Music, television, or other technical devices were not available to the subjects during exercise. All participants performed exercise session successfully. PET scan began within 15—36 min after the completion of the exercise session. fMRI scan took place immediately after the 51 minute PET scans. On the day of the rest scan, the participants rested passively for 60 minutes before the scans without reading, music, television, or mobile entertaining devices.

Subjective appetite sensations (e.g. hunger, satiation, fullness) were recorded using visual analogue scales (VAS) (Flint, Raben, Blundell, & Astrup, 2000) with extreme statements anchored at each end (i.e. not at all hungry to extremely hungry). Subjective feelings of pleasant versus unpleasant emotions were measured using the Positive and Negative Affect Schedule (PANAS) (Watson, Clark, & Tellegen, 1988) and VAS (separate scales for tension, irritation, pain, exhaustion, satisfaction, motivation to exercise, euphoria, and energy), and subjective levels of stress using the Perceived Stress Questionnaire (PSQ) (Levenstein et al., 1993). The VAS, the PANAS, and the PSQ were administered at the beginning of trials (exercise/rest), and after the fMRI scans. The VAS and the PANAS were
Corresponding Author: Dr. Jussi Hirvonen

also administrated immediately after exercise. Borg’s rating of perceived exertion (6-20) scale was used to measure participants’ subjective exertion during exercise prior to and in every fifteen minutes of training.

PET data acquisition and analysis

Data were acquired at Turku PET Centre as described previously (Saanijoki et al., 2018). Briefly, MOR availability was measured with the high-affinity agonist radioligand $[^{11}\text{C}]$carfentanil, synthesized as previously described (Hirvonen et al., 2009; Saanijoki et al., 2018). After an intravenous bolus injection of $[^{11}\text{C}]$carfentanil (targeted 250 MBq, mean 256 (SD 14) MBq), brain radioactivity was measured with the 3T Philips Ingenuity TF PET/MR (Philips Healthcare, Cleveland, OH, USA) scanner for 51 min, using 13 frames, with in-plane resolution of 3.75 mm. The injected radioligand doses were similar between the scans (exercise: 258.6 (SD 13.0) MBq; rest: 252.5 (SD 14.1) MBq). Radioactivity data acquisition started concomitantly with the injection of $[^{11}\text{C}]$carfentanil.

Alignment and coregistration were performed using SPM8 software (www.fil.ion.ucl.ac.uk/spm/) running on Matlab R2012a (MathWorks) as previously described (Saanijoki et al., 2018). Receptor availability was expressed in terms of $BP_{\text{ND}}$, which is the ratio of specific to nondisplaceable binding in the brain, using occipital cortex as the reference region. Simplified reference tissue model (SRTM) was used to obtain voxel-wise $BP_{\text{ND}}$ estimates using occipital time activity curve as reference tissue input (Gunn et al, 1997). $BP_{\text{ND}}$ is not confounded by differences in peripheral distribution, and specific binding of $[^{11}\text{C}]$carfentanil is unaffected by changes in cerebral blood flow (Endres, Bencherif, Hilton, Madar, & Frost, 2003; Frost et al., 1989; Liberzon et al., 2002). The resulting subject-wise parametric $BP_{\text{ND}}$ images were normalized into MNI space using deformation fields obtained by segmenting the T1-weighted images, and smoothed with a Gaussian kernel of 7 mm full-
Corresponding Author: Dr. Jussi Hirvonen

width half-maximum (FWHM). Due to technical problems with the PET scanner, one exercise scan was subsequently found to be invalid and was excluded from the analysis.

Experimental design for fMRI

Experimental design for fMRI is summarized in Figure 2. The stimuli were full-colour images of palatable foods (e.g. pizza, chocolate cake, sundae), non-palatable foods (e.g., crackers, cabbage, aubergine), and cars matched with respect to low-level visual features such as mean luminosity, RMS contrast and global energy. In this stimulus set, palatable foods are consistently rated as more pleasant than the non-palatable foods, t(28) = 10.97, p < 0.001 (Nummenmaa et al., 2012). During the fMRI acquisition the participants viewed alternating 15.75-second epochs with six stimuli from one category (palatable foods, non-palatable foods, or cars), each shown for 1 s and intermixed with fixation cross visible for a random time (0.75 – 1.75 s; mean = 1.25 s). A stimulus epoch with car pictures was always presented between the palatable and non-palatable stimulus epochs to maximize the power of the design by reducing the reward system activity between the food epochs. The images were placed slightly to the left or to the right of the screen, and the participants were instructed to press the left or right response button according to which side the stimulus was presented. This ensured that the participants paid attention to the stimuli while rendering their reward value processing implicit. The order of the stimuli during each epoch was randomized. Altogether there were a total of 72 palatable food trials (in 12 epochs), 72 non-palatable food trials (in 12 epochs) and 144 car trials (in 24 epochs). The starting epoch of the task was counterbalanced across participants. Total task duration was 14 minutes. The fMRI task started 80–110 min after the cessation of exercise.

fMRI data acquisition
Corresponding Author: Dr. Jussi Hirvonen

The fMRI scan took place after the PET scan. MR imaging was performed with the 3T Philips Ingenuity TF PET/MR scanner. Whole-brain functional data were acquired with echo-planar imaging (EPI) sequence, sensitive to the blood-oxygen-level-dependent (BOLD) signal contrast (TR=2000 ms, TE=20 ms, 75° flip angle, FOV 240 x 240 x 140 mm, 80 x 80 acquisition matrix, 53.4 kHz bandwidth, 3 mm x 3 mm in plane matrix and 4.0 mm slice thickness, 35 slices acquired in ascending order with no gaps between slices). A total of 430 functional volumes were acquired, and the first 5 volumes were discarded to allow for equilibration effects. A T1- weighted (TR 8.1 ms, TE 3.7 ms, flip angle 7°, scan time 263 s, 1 mm³ voxel size) MR images were acquired for anatomical reference.

Data were preprocessed and analysed using SPM8 software. The EPI images were first sinc interpolated in time to correct for slice time differences and realigned to the first scan by rigid body transformations to correct for head movements. EPI and structural images were coregistered, T1 images were normalized to the T1 standard template in MNI space using linear and non-linear transformations, these warps were then applied to the EPI images. Finally, EPI images were smoothed with a Gaussian kernel of FWHM 8 mm.

Analysis of regional effects

A whole-brain random effects model was applied using a two-stage process (first and second level). This random-effects analysis assesses effects on the basis of inter-subject variance and thus allows inferences at population level. For each participant, we used a GLM to assess regional effects of task parameters on BOLD indices of activation. The model included three experimental conditions (palatable foods, non-palatable foods, and cars) and effects of no interest (six realignment parameters) to account for head-motion-related variance. Low-frequency signal drift was removed using a high-pass filter (128 s), and AR(1) modelling of temporal autocorrelations was applied. Subject-wise contrast images were generated using the
Corresponding Author: Dr. Jussi Hirvonen

contrast palatable minus non-palatable foods. To test the exercise-dependent changes in anticipatory reward, we modelled the interaction contrasts (palatable versus non-palatable foods) × (rest versus exercise) and (foods versus cars) × (rest versus exercise). The second level analysis used these contrast images in a new GLM, and generated statistical images, that is, SPM-t maps. With balanced designs at first level this second level analysis closely approximates a true mixed effects design, exhibiting both within and between subject variance. Data were thresholded at p < 0.01, false discovery rate (FDR) corrected at the cluster level.

Fusion analysis of PET, fMRI, and self-reports data

To estimate the effects of exercise-induced changes in regional MOR availability on anticipatory reward responses to palatable foods in fMRI, we generated anatomical regions of interest (ROIs) in key components of the reward circuit (ventral striatum, dorsal caudate nucleus, putamen, amygdala, thalamus, insula, orbitofrontal cortex, and anterior, middle, and posterior cingulate cortex) using the AAL (Tzourio-Mazoyer et al., 2002) and Anatomy (Eickhoff et al., 2005) toolboxes. Subsequently, subject-wise $BP_{ND}$ were extracted for each (ROI) from rest and exercise conditions using Marsbar toolbox for SPM (http://marsbar.sourceforge.net/), and the difference scores (exercise minus rest) were used in full-volume linear regression analysis to predict the voxel-wise contrast estimates (SPM contrast images) for the interaction contrasts (palatable vs. non-palatable foods) × (rest vs. exercise) and (foods versus cars) × (rest versus exercise). Because of high between-regions co-dependency of $[^{11}\text{C}]$carfentanil binding potentials (Tuominen et al., 2015; Tuominen, Nummenmaa, Keltikangas-Järvinen, Raitakari, & Hietala, 2014), each ROI was used as a predictor in a separate model. The results were thresholded at p < 0.05, FDR corrected at cluster level.
Corresponding Author: Dr. Jussi Hirvonen

Self reported weekly physical activity minutes, maximal oxygen uptake, maximal workload and BMI, as well as subjective appetite sensations and perceptual and affective scores (post minus pre exercise) were used in full-volume linear regression analysis to predict the voxel-wise contrast estimates (SPM contrast images) for the interaction contrasts (palatable vs. non-palatable foods) × (rest vs. exercise) and (foods versus cars) × (rest versus exercise). Furthermore, the associations between self-report data and changes in MOR binding were assessed using an exploratory whole-brain analysis. The results were thresholded at p < 0.05, FDR corrected at cluster level.

Statistical analyses

Behavioural data were analysed with IBM SPSS Statistics 24 for Mac OS X (IBM Corp., Chicago, IL, USA). The normality assumption was tested with a Shapiro–Wilk test. Because of positively and negatively skewed distributions, perceived stress, PANAS negative, tension, irritation, and pain values were log-transformed, and motivation $x^2$-transformed prior to statistical analyses. Perceptual, affective, and appetite responses within and between scan sessions were analysed using repeated-measures ANOVA. Nonsphericity was estimated with Mauchley’s test, and when the criteria were not met, the Greenhouse–Geisser correction was applied. Paired samples t test (pre / post exercise) was used to analyse the acute effects of exercise on affective and appetite responses. An alpha level of p ≤ 0.05 and two-sides tests was used in all statistical testing.

RESULTS

Perceptual, affective, and appetite responses
Corresponding Author: Dr. Jussi Hirvonen

Exercise was perceived as “somewhat hard” (mean Borg’s RPE = 13.7 SD 1.9). Hunger, prospective food consumption, food cravings, and exhaustion increased ($F_{1,23} = 188.58, p < 0.001; F_{1,23} = 77.895, p < 0.001; F_{1,23} = 51.701, p < 0.001; F_{1,22} = 6.55, p = 0.018$, respectively) and fullness, satiety, and positive and negative affect decreased ($F_{1,23} = 69.736, p < 0.001; F_{1,23} = 111.01, p < 0.001; F_{1,22} = 18.102, p < 0.001; F_{1,22} = 8.925, p = 0.007$, respectively) after the scans, but not differently between rest and exercise conditions. Acutely, exercise increased sensations of euphoria ($p < 0.001$) and pain ($p = 0.04$) and the ratings of hunger ($p < 0.001$), prospective food consumption ($p = 0.004$), desire to eat ($p = 0.014$) and reduced satiety ($p = 0.013$).

Regional effects in fMRI

Across all subjects, neuronal response to foods versus cars was observed in network of brain regions, including the supplementary motor area, sensory motor and premotor cortices, and parietal cortices (Fig. 3). Higher responses to cars versus foods were observed in the visual cortex. Contrasting palatable versus non-palatable foods resulted in robust activation of the reward circuit (Fig. 3). Activation foci were observed in the medial prefrontal cortex, bilateral caudate, bilateral hippocampus, posterior cingulate, bilateral fusiform, and precuneus. However, no differences between rest and exercise conditions were found even with a more lenient threshold $p < 0.005$ uncorrected, $k = 50$.

Exercise-induced reduction in fullness (Fig. 4A) and increase in prospective food consumption (Fig. 4B) predicted higher responses to palatable versus non-palatable foods in exercise compared with rest. Additionally, higher ratings of perceived exertion during exercise (Fig. 4C) and increased positive affect after exercise (Fig. 4D) predicted higher responses to palatable versus non-palatable foods after exercise compared with rest. Furthermore, more physical activity per week (Fig. 5A) and higher maximal oxygen uptake
Corresponding Author: Dr. Jussi Hirvonen

(Fig. 5B) predicted lower responses to foods versus cars in exercise compared with rest (all p < 0.05, FDR corrected).

Effects of exercise on MOR binding

We previously reported that there are no significant differences in $[^{11}\text{C}]$carfentanil $B_{\text{ND}}$ values between rest and moderate-intensity exercise conditions at group level analysis (Saanijoki et al., 2018). To examine if exercise-induced regional changes in MOR availability would be associated with changes in anticipatory reward responses measured with fMRI, the BOLD responses to palatable versus non-palatable foods and foods versus cars in exercise versus rest condition were predicted with regional $B_{\text{ND}}$ difference in each ROI. We found that the exercise-induced change in MOR availability in eight out of ten ROIs (i.e. ventral striatum, dorsal caudate nucleus, putamen, amygdala, thalamus, orbitofrontal cortex, and middle, and posterior cingulate cortices) correlated negatively with the difference between exercise and rest conditions in BOLD responses to palatable versus non-palatable foods. These findings indicate a correlation between increased exercise-induced opioid release and higher brain responses to palatable versus non-palatable foods. The effect was observed in widespread brain regions including both cortical regions, i.e. prefrontal cortex, anterior cingulate cortex, and insula, as well as subcortical regions, i.e. hippocampus, thalamus, amygdala, ventral striatum, periaqueductal gray matter in the brainstem, and cerebellum, as shown in cumulative activation map in Figure 6A and Figures 7A-B. No opposite correlations were found.

Similarly, the exercise-induced change in MOR availability in four out of ten ROIs (i.e. ventral striatum, dorsal caudate nucleus, putamen, and orbitofrontal cortex) correlated negatively with the difference between exercise and rest conditions in BOLD responses to foods versus cars indicating a correlation between increased exercise-induced...
Corresponding Author: Dr. Jussi Hirvonen

opioid release and higher responses to food versus non-food objects. The effect was observed in frontal, temporal, parietal and occipital cortices, anterior and middle cingulate, supplementary motor areas, and left thalamus and caudate (Fig. 6B).

Decreased MOR binding after exercise predicted increased hunger and prospective food consumption (Fig. 8A-B) and decreased fullness and satiety (Fig. 8C-D) after exercise.

DISCUSSION

Our results reveal a novel role for brain µ-opioid receptors in modulating anticipatory food reward following aerobic exercise. We demonstrate that changes in endogenous opioid release (indicated by the changes in MOR availability measured with PET) after exercise are associated with changes in brain responses to foods versus non-foods, and to palatable versus non-palatable foods after exercise as measured using fMRI. Subjects who showed larger opioid release following exercise showed largest increase in the anticipatory reward responses following exercise. This effect was observed in multiple brain regions implicated in reward processing, including ventral striatum, medial prefrontal cortex, anterior cingulate, and insula. These findings suggest that individual variation in hedonic and motivational processing of food acutely after exercise may be modulated by exercise-induced changes in the brain opioid system.

Opioid receptors and peptides are expressed throughout the human reward and reinforcement circuit (Le Merrer, Becker, Befort, & Kieffer, 2009; Nummenmaa & Tuominen, in press) and opioidergic action is involved in hedonic and motivational processing of food (Mendez, Ostlund, Maidment, & Murphy, 2015; Peciña & Smith, 2010). We previously found evidence for opioid modulation in physical exercise. High-intensity
Corresponding Author: Dr. Jussi Hirvonen

exercise induced opioid release, whereas moderate-intensity exercise resulted in highly
variable MOR responses between subjects: at the group level, no significant net changes in
opioid release was observed, however involvement was suggested by correlations with
exercise-induced euphoria (Saanijoki et al., 2018). Here, we did not find changes in
anticipatory reward following exercise, but the change in MOR binding after moderate-
intensity exercise was associated with altered processing of anticipatory food reward between
rest and exercise conditions. Thus, our combined multimodal analysis of the PET and fMRI
data revealed that subjects who showed most increases in endogenous opioid release also had
highest anticipatory fMRI reward responses following the exercise session. These data are
consistent with previous work showing that stimulation of MORs increases food consumption
and preference for palatable foods both in animals and humans, whereas conversely blocking
opioid receptors with opioid antagonist reduces motivation towards high-calorie food
consumption (Cambridge et al., 2013; Giuliano, Robbins, Nathan, Bullmore, & Everitt, 2012),
and also go beyond these data to suggest a role of physical exercise.

Given that physical exercise is rewarding itself, habitual exercise has been
proposed to buffer the drive for other rewards such as palatable foods (Joseph, Alonso-
Alonso, Bond, Pascual-Leone, & Blackburn, 2011) or illicit drugs (Lynch, Peterson, Sanchez,
Abel, & Smith, 2013). In animals, chronic voluntary wheel running reduces exogenous MOR
agonist stimulated food intake (Liang, Bello, & Moran, 2015) and long-term exercise also
decreases methamphetamine seeking behaviour (Sobieraj, Kim, Fannon, & Mandyam, 2016)
and the reinforcing effects of cocaine (Smith, Schmidt, Iordanou, & Mustroph, 2008). Taken
together these findings suggest that exercise may alter the reward processing, and thus may be
a potent behavioural intervention that supports treatment of addictions and substance abuse.
Our findings, however, suggest that exercise acutely enhance reward processing given
sufficient opioidergic activation. This accords with prior work demonstrating reward-
Corresponding Author: Dr. Jussi Hirvonen

sensitizing action of acute exercise on eating in rats (Lett, Grant, & Gaborko, 1996). Whether continuous physical exercise is able to increase MOR availability and thereby reduce anticipatory food reward responses in humans remains to be determined.

Hedonic aspects of foods motivate feeding and may also lead to overeating and weight gain. Previous fMRI studies have found that individuals who show greater neuronal activation to high-caloric food pictures consume more snacks after the experiment (Lawrence, Hinton, Parkinson, & Lawrence, 2012), have higher BMI (Stoeckel et al., 2008) and poorer weight loss outcomes (Murdaugh, Cox, Cook, & Weller, 2012). Accordingly, reward circuit sensitivity to anticipatory cues is predictive of actual food consumption and weight gain/loss outcomes. Physical exercise may however interfere with food reward processing. Aerobic exercise decreases neuronal responsiveness to high-caloric foods vs. non-foods in bilateral insula and increases responsiveness in left precuneus (Evero et al., 2012), whereas high-intensity exercise decreases neuronal activation to images of high caloric foods vs. non-foods in orbitofrontal cortex (OFC) and left hippocampus and increases activation in dorsolateral prefrontal cortex (DLPFC) (Crabtree et al., 2014) immediately (within ten minutes) after exercise completion. Longer periods between exercise and fMRI may compromise the detection of such effects, as no change in haemodynamic responses to images of food between exercise rest was found, when fMRI took place after 30 min of completion of exercise (Cornier et al., 2012). Consequently, our study may have missed some of the effects of exercise on brain responses due to the 51 min PET scan prior to fMRI measurement. Nevertheless, variability in palatable food anticipation responses between rest and exercise conditions was explained by exercise-induced change in MOR availability. Interestingly, six-month exercise intervention (5 days per week) in obese individuals resulted in reduced responses to visual food cues, yet these effects were blunted by an acute bout of aerobic exercise (Cornier et al., 2012), which, according to our present findings, might be explained
by exercise-induced MOR action. Given that exercise-induced opioid release depends on exercise intensity and duration (Saanijoki et al., 2018; Schwarz & Kindermann, 1992), the differences in opioid action may well account for divergent neuronal responses to visual food cues found in different studies with various exercise sessions. While BMI, physical activity level and cardiovascular fitness may contribute to MOR tone, the underlying causes of diverse opioidergic responses to moderate-intensity exercise warrant further research.

Methodological considerations

Decrease in $BP_{ND}$ is often interpreted as evidence of increased concentration of endogenous neurotransmitter, according to the competition principle. This principle has been most robustly established for the dopamine system (Laruelle, 2000) but has been more recently used also for the µ-opioid system (Colasanti et al., 2012; Mick et al., 2014, 2016). Although we found significant correlations between exercise-induced change in $BP_{ND}$ and change in anticipatory food reward activations, not all subjects demonstrated decreased $BP_{ND}$ consistent with endogenous opioid release; in fact, most subjects showed increased $BP_{ND}$ after exercise. Such increase in $[^{11}]$carfentanil binding has been suggested to reflect MOR “deactivation” (Nummenmaa et al., 2016; Zubieta et al., 2002), presumably due to acute decrease in synaptic endogenous opioids. Alternatively, increased radioligand binding reflects increased number of available receptors or increased binding affinity. Regardless of whether bidirectional changes in $[^{11}]$carfentanil binding truly reflect commensurate fluctuations in endogenous opioid concentration or changes in MOR binding affinity, our results are consistent with a modulatory role of MOR in exercise-induced changes in anticipatory food reward responses.

We studied only young lean (non-obese) men, and because age, obesity, and sex influence both MOR availability and the capacity to activate the MOR system (Burghardt et

al., 2015; Gabilondo, Meana, & García-Sevilla, 1995; Karlsson et al., 2015; Zubieta et al., 2002; Zubieta, Dannals, & Frost, 1999), our results may not directly generalize to females and other age and weight groups. Also, we studied strictly anticipatory reward processing and no actual foods/rewards were delivered in the study. Although the exercise-induced alterations in the hedonic processing of food have been linked with food intake (Finlayson et al., 2009), whether our results also translate to food consumption remains to be determined.

Conclusions

We conclude that changes in MOR binding correlates with anticipatory food reward responses after exercise, such that subjects who show evidence of opioid release tend to have higher functional responses. Our data suggest that acute exercise-induced MOR action may modulate appetitive motivation and contribute to anticipatory reward sensitization by enhancing food reward, and consequently account for compensatory eating following exercise.

FIGURE LEGENDS

**Figure 1.** Timeline for experimental sessions. Subjects underwent two PET and fMRI scans on separate days: after rest and after exercise. The order of the scans was counterbalanced across subjects. Affective and perceptual responses were measured at the beginning of each session and after the scans and additionally during and after exercise. Changes in BP_{ND} (exercise minus rest) measured with PET were used to predict changes in BOLD (exercise minus rest) measured with fMRI. RPE, rating of perceived exertion; PANAS, Positive and Negative Affect Schedule; VAS, visual analogue scale; PSQ, perceived stress questionnaire.

**Figure 2.** Experimental design for fMRI. Participants viewed alternating 15.75-s epochs with palatable foods, non-palatable foods or cars. Each block contained 6 stimuli from one category, intermixed with fixation crosses.

**Figure 3.** Brain regions where BOLD-fMRI responses were larger when viewing palatable versus non-palatable foods (orange) and when viewing foods versus cars (blue). The data are thresholded at p < 0.01, FDR corrected at cluster level.

**Figure 4.** Exercise-induced reduction in fullness (A) and increase in prospective food consumption (B) as well as higher mean rating of perceived exertion during exercise (C) and increased positive affect after exercise (D) predicted higher responses to palatable vs. non-palatable foods in exercise compared with rest (p < 0.05, FDR corrected). The scatterplots show least-square regression lines with 95% confidence intervals and are shown for visual purposes only, statistical inference is based on the full-volume SPM analysis.

**Figure 5.** Higher self-reported physical activity minutes per week (A) and higher maximal oxygen uptake (B) predicted lower responses to foods versus cars in exercise compared with rest (p < 0.05, FDR corrected). The scatterplots show least-square regression lines with 95% confidence intervals and are shown for visual purposes only, statistical inference is based on the full-volume SPM analysis.

**Figure 6.** Cumulative maps showing the number of ROIs (out of 10) whose $[^{11}\text{C}]$carfentanil BP$_{ND}$ was correlated (p < 0.05, FDR corrected) with BOLD responses to (A) palatable versus non-palatable foods between exercise and rest conditions and to (B) foods versus cars between exercise and rest conditions.

**Figure 7.** Brain regions where exercise-induced change in thalamic MOR availability is associated with the difference in BOLD-fMRI responses to palatable versus non-palatable foods between exercise and rest conditions (A), and where exercise-induced change in MOR availability in dorsal caudate is associated with the difference in BOLD-fMRI responses to palatable versus non-palatable foods between exercise and rest conditions (B). The scatterplots show least-square regression lines with 95% confidence intervals and are shown for visual purposes only, statistical inference is based on the full-volume SPM analysis.

**Figure 8.** Whole brain exploratory analysis revealed that exercise-induced change in MOR binding correlated negatively with increased hunger (A) and prospective food consumption (B) and positively with decreased fullness (C) and satiety (D). Negative change in BP$_{ND}$ is consistent with increased endogenous opioid release. The scatterplots show least-square regression lines with 95% confidence intervals and are shown for visual purposes only, statistical inference is based on the full-volume SPM analysis.
